ABSTRACT

Today customers require software systems to provide particular levels of qualities, while operating under dynamically changing conditions. These requirements can be met with different self-adaptation approaches. Recently, we developed two approaches that are different in nature — control theory-based SimCA and architecture-based ActivFORMS — to endow software systems with self-adaptation, providing guarantees on desired behavior. However, it is unclear which of the two approaches should be used in different adaptation scenarios and how effective they are in comparison to each other. In this paper, we apply SimCA and ActivFORMS to the Tele Assistance System (TAS) exemplar and compare obtained results, demonstrating the difference in achieved qualities and formal guarantees.

1. INTRODUCTION

The burden on software developers has drastically increased in recent years as customers expect software to cope with continuous change. They expect the software to run seamlessly on different platforms, deal with varying resources, and adapt to changes in system goals. Often, these runtime changes are difficult to predict, requiring software engineers to design the software with incomplete knowledge.

Self-adaptation is widely encouraged to handle software design with incomplete knowledge [4, 7]. A classic approach to realize self-adaptation is architecture-based adaptation [15, 13], where a system maintains an explicit architectural model of itself, reasons about this model, and adapts itself to particular adaptation goals when relevant changes occur. However, achieving guarantees of the system behavior with architecture-based adaptation is hard [3]. For this reason adaptation mechanisms based on control theory [10, 9] attracted the attention of self-adaptive systems community.

Recently, we developed two approaches for runtime adaptation, one from each of the mentioned fields: ActivFORMS (Active Formal Models for Self-adaptation) [11] an architecture-based approach, and SimCA (Simplex Control Adaptation) [16] that is based on principles from control theory and linear optimization. In this paper, we present a comparative evaluation of SimCA and ActivFORMS on a set of scenarios. To the best of our knowledge, no systematic comparison between approaches for runtime adaptation based on control theory and architecture-based adaptation has been performed so far. We compare obtained results of runtime adaptation (the system output), and we analyze the provided guarantees and system behavior in the presence of disturbances.

The evaluation is conducted using the TAS exemplar [17]. TAS provides remote health support to patients by composing a number of services. Each service can be implemented by multiple providers. These implementations have different reliability, performance and cost, which affect the overall quality of the application. Choosing a concrete service provider to ensure the required quality of service (QoS) at runtime is a key factor to adaptation of service-based systems as TAS.

The remainder of the paper is structured as follows. An adaptation scenario with the TAS exemplar is introduced in Section 2. Section 3 summarizes the two studied adaptation approaches: SimCA and ActivFORMS. In Section 4 these two approaches are applied to TAS and compared in multiple scenarios. Section 5 provides discussion of received results. Finally, conclusions and directions for future research are presented in Section 6.

2. ADAPTATION SCENARIO: TAS

In this section, we introduce a scenario of TAS used for evaluating SimCA and ActivFORMS. The main goal of TAS is to track a patient’s vital parameters in order to adapt the drug or drug doses when needed, and take appropriate actions in case of emergency. To satisfy this goal, TAS combines three types of services in a workflow, shown on Figure 1.

Each incoming request is first processed by the Medical Service. This service receives messages from patients with their...
The system requirements are the following:

R1. The average failure rate should not exceed 0.03%.
R2. The average response time should not exceed 26 ms.
R3. Subject to R1 and R2, the cost should be minimized.

The requirements R1-R3 as well as the properties of the services may change at runtime and the system should adapt accordingly. The adaptation task is to decide, for each incoming request, which combination of services to select in order to continuously satisfy the goals.

The system design assumes that the goal failure rate is not dropped and can be sent to the same or another service provider for re-execution. Hence, the goal failure rate is lower than the rates of individual implementations.

2.1 The adaptation problem

Generalizing from the concrete TAS scenario, the adaptation problem we are aiming to solve is the following:

Maintain a desired level of quality for multiple goals and optimize the solution according to another goal, regardless of possible fluctuations in the system parameters, measurement accuracies, requirement changes, and dynamics in the environment that are difficult to predict.

Defining and developing such an adaptive solution introduces several key challenges. First, the appropriate sensors (measured variables) and actuators (knobs that can influence the software behavior) must be carefully chosen. Second, the software system must be properly modeled. Finally, the appropriate adaptation mechanism that achieves the goals, rejecting external disturbances and optimising the solution according to additional goal, must be developed. The following section describes two approaches that tackle these challenges.

3. STUDIED APPROACHES

3.1 SimCA

The adaptation logic of SimCA consists of multiple SISO controllers that independently compute control signals for each of the goals, and a simplex block that receives the control signals as input and produces an output that is used for adapting the software system. Figure 2 schematically shows the primary building blocks of SimCA.

A detailed explanation of SimCA is available in [16]. In short, each system goal (reliability, performance) except cost is represented as a setpoint $s_i(k)$. On every adaptation step $k$ the system outputs $O_i(k)$ are measured. Based on the error $e_i(k) = s_i(k) - O_i(k)$ and a linear model $M_i$, described below, each controller $C_i$ produces a signal $u_i(k)$ which represents the value of each goal that should be reached by the system. The simplex block receives $u_i(k)$ and additional environment/plant parameters (e.g., the invocation cost of external services) as inputs and produces a simplex signal $u_{sx}(k)$ as output. $u_{sx}(k)$ contains the values of system knobs which affect the plant behaviour. For TAS, $u_{sx}(k)$ is a vector containing the probabilities to select each of the available service providers. Disturbances affecting $O_i(k)$ are handled by controller $C_i$ via adjusting the control signal $u_i(k)$.

SimCA works in three phases: identification, control, and optimization.

In the identification phase, $n$ linear models of the controlled system are built. Each model $M_i$, $i \in [1, n]$, is responsible for one goal $s_i$. The identification phase starts by feeding all possible control signal values to the plant. The goal of identification is to determine the influence of control signal $u_i$ on the corresponding system output $O_i$ at every time step.
The dependency between $u_i$ and $O_i$ is captured by the coefficient $\alpha_i$ which is further used to build controller $i$. $\alpha_i$ is calculated during identification based on linear regression using the APRE tool [14]. As a result, the following set of linear models is obtained:

$$O_i(k) = \alpha_i \times u_i(k - 1) \quad (M_i)$$

In $M_i$, the control signal is a value from the interval $[\min_i, \max_i]$, where $\max_i$ and $\min_i$ are the maximal and minimal values that can be achieved by TAS for the $i$-th goal:

$$u_i(k) = (\max_i - \min_i) \times \eta_i(k) + \min_i \quad (1)$$

$\eta_i$ is the control coefficient. During the identification phase, $\eta_i$ changes from 0.0 to 1.0 using an increment of 0.05 on every step $k$. As a consequence, most feasible values of goal $i$ are produced as $u_i$. This allows us to measure all the possible values of the outputs $O_i(k)$, calculate $\alpha_i$, and build $M_i$.

The model $M_i$ generally describes the system behavior but does not take into account small disturbances or sudden failures that typically occur in software systems. To deal with inaccuracies in $M_i$, SimCA uses a Kalman filter to adapt the model at runtime, and a change point detection mechanism that allows reacting to critical changes in the system.

An important note concerning the control methodology of SimCA is that the simplex method does not change the value of control signal $i$. Instead, simplex is responsible for seamless translation of control signals into a proper actuation signal. For example in TAS, if the control signal equals to failure rate $= 0.03$, simplex finds a combination of services (SI-S9) that assures this failure rate is not exceeded. Hence, simplex is not considered when building a system model and synthesizing controllers that manage this model. Instead, controllers are assumed to affect the plant output via control signals. Every goal is controlled separately during the first two phases of SimCA. This means that during identification and control phases SimCA works in parallel with multiple Single-Input-Single-Output (SISO) controllers, and then combines control outputs with the help of simplex during optimization phase.

In the control phase, a set of $n$ controllers is synthesized. Each controller $C_i$ is responsible for the $i$-th goal. $C_i$ calculates the control coefficient $\eta_i$ at the current time step $k$ depending on the previous control coefficient $\eta_i(k - 1)$, adjustment coefficient $\alpha_i$, controller pole $p_i$ and the error $e_i$:

$$\eta_i(k) = \eta_i(k - 1) + \frac{1 - p_i}{\alpha_i} \times e_i(k) \quad (2)$$

The controller pole $p_i$ belongs to the open interval $(0,1)$ to maintain stability and avoid oscillations. The pole also allows to trade-off robustness to external disturbances with the convergence speed (known as settling time): higher values of $p_i$ lead to slower convergence [8].

In the optimization phase, SimCA combines the signals $u_i(k)$ from multiple controllers using the simplex method to optimally drive the measured output of the system towards its desired behavior. Simplex solves the following problem:

Minimize Cost: $\min C = \sum_{j=1}^{p} c_j \cdot x_j$

subject to:

$$\sum_{i=1}^{n} \sum_{j=1}^{p} a_{ij} \cdot x_j = u_i$$

$$x_j \geq 0, u_i \geq 0, \text{with } i = 1 \ldots n, j = 1 \ldots p$$

where:

- $p$: a number of variables — each variable represents one service provider;
- $n$: a number of equations — each equation represents a goal to be satisfied;
- $x_j$ are the values of system knobs, i.e. probabilities to select each of the service providers;
- $u_i$ are the control signals;
- $a_{ij}$ and $c_j$ are the monitored parameters: the failure rate, response time and cost of external services.

SimCA finds the variables of the problem $x_j$ and passes them to the plant in the form of a simplex signal. A detailed explanation on how simplex solves the system of equations (3) can be found in [16], and additional background in [5].

### 3.2 ActivFORMS

ActivFORMS is an architecture-based approach for self-adaptation that uses an integrated formal model of the adaptation components of the feedback loop and the knowledge they share [11]. ActivFORMS distinguishes itself from existing architecture-based approaches in three ways:

- The formally verified model of the feedback loop is directly executed by the virtual machine, hence called the active model. This allows to guarantee at runtime the system properties verified at design time. As the active model is directly executed, the approach does not require coding.
- ActivFORMS supports dynamic changes of the active model. A new feedback loop model can be deployed at runtime to meet new or changing goals.
- ActivFORMS supports goal management and model verification at runtime.

ActivFORMS follows a three-layered reference model proposed by Kramer and Magee [13], see Figure 3. The bottom layer comprises the managed system that implements the domain-specific functionality. The active model monitors and adapts the managed system through probes and effectors respectively. The goal management layer monitors the active model and environment, and deals with adaptation issues that cannot be handled by the current active model; e.g., it dynamically changes the active model to deal with changing system goals.

The active model realizes a MAPE-K (Monitor-Analyze-Plan-Execute-Knowledge) feedback loop [12] that monitors the managed system and adapts it according to the system goals. ActivFORMS supports feedback loops modeled using networks of timed automata. A timed automaton is a finite-state machine that models a behavior, extended with clock variables.

Recalling the TAS scenario, we used a utility function as a part of the planner component of a MAPE-K formal model to provide the required adaptation, see Figure 4. When triggered by a signal from the analysis component, the planner calculates the utility function coefficients and sends a signal to the execution component to update the managed system.

\( \text{min}_{\text{cost}} \). On every
on a basic TAS scenario and
in response to different runtime changes. Finally, Section 4.3
discusses guarantees provided by both approaches.

4.1 Experimental setting
We use the TAS case described in Section 2 to compare the
adaptation approaches. The TAS example [17] is realized as a
Java application and extended with SimCA and ActivFORMS
classes. The starting parameters of the services and system
requirements are specified in Table 1.

Adaptation is performed once per 100 invocations of TAS (\( k = 100 \) inv.). At each adaptation step the calculation calculates
the average measured value of the \( i \)-th goal (e.g., measured
failure rate) during the past 100 inv. Then it calculates error
in SimCA is set to 0.98 which allows to reject errors of
in SimCA is set to 0.98 which allows to reject errors of
high magnitude. For the same reason, the cost increment \( \Delta C \)
in ActivFORMS is set to a low value of 0.1\( \epsilon \) 4.

The application collects the data of the system and the ser-
vice implementations to build performance graphs, which are
used to compare the adaptation approaches in the following
section. The \( x \)-axis of the graphs are time instants \( t \), each
instant corresponds to a series of \( \Delta t \) inv. of TAS. Thus, the
\( y \)-axis shows the average values of the measured feature per
\( \Delta t \) inv. of TAS. \( \Delta t \) can be changed in the TAS interface.

4.2 Adaptation results
The graphs in Figure 5 show adaptation results of SimCA
and ActivFORMS on TAS configured according to Table 1.

4We use \( \epsilon \) symbol to represent cost throughout the paper.
AS1 and AS3. A combination of S2, S4 and AS3, while ActivFORMS uses S2, approximately equal amount of times (\(\tau\) times less time in order to reach a setpoint. As for the picked graphs, it is notable that the latter approach requires three

reliability error and a small performance error after \(t=30\). So in this case SimCA needs 4

adaptation period that leads to high measurement errors. After \(t=30\), the measured reliability spikes are almost equal on the top plots, however performance and probabilities to select services in ActivFORMS have noticeably higher oscillation amplitude than in SimCA. Such effect is caused by the nature of the algorithm that selects utility function coefficients: the closer the measured value of a goal \(i\) gets to the setpoint \(i\), the lower is the priority of goal \(i\).

It is worth mentioning that simplex operating under disturbances has the property of distributing probabilities for selecting services equally among all available services [16]. We do not observe this behaviour in the solution with ActivFORMS.

With ActivFORMS, the probabilities of selecting some of the services can suddenly change from 0 to 100% in 1000 workflow invocations (e.g., see the probability to select S2 in 30 < \(t < 40\). Hence, with SimCA, the load on service providers will be relatively smooth over time, while the load with the ActivFORMS solution can change abruptly, requiring the service providers to keep 100% of their resources available all the time.

Both adaptation approaches have a mechanism that allows to trade-off settling time for other properties, so we study how such trade-off will affect the system output, see Figure 7.

Lowering pole \(p\) in SimCA from 0.98 to 0.7 drastically increases the oscillation amplitude of all outputs. After \(t=40\) the system even triggers re-identification as the measured system output values are too far from their setpoints. This is caused by a combination of low settling time (i.e., the system immediately follows any change in the output) and small adaptation period that leads to high measurement errors.

Raising the cost increment \(\Delta C\) in ActivFORMS from 0.1 to 1.0 also increases oscillations of all system outputs. However, their amplitude is much lower, see the ‘Reliability’ and ‘Cost’ plots. The system is also more stable than in SimCA. This experiment allows to conclude that ActivFORMS is a better
adaptation solution for a system with settling time priority.

Finally, we show how both approaches react to runtime changes, see Figure 8. First of all, having the same initial conditions as in the previous experiments, we set ActivFORMS’ cost setpoint to 11.0e instead of 8.5e because we already know the approximate optimal cost value. This adjustment results almost immediately in convergence to the desired setpoint values. Hence, by doing a system pre-run or offline validation, the ActivFORMS adaptation time can be greatly decreased.

Coming back to Figure 8, there are three major changes happening in the system at runtime:

- **Goal change.** Both goals are changed at t=22: failure rate from 0.03 to 0.05%, resp.time from 26 to 28 ms;
- **Abrupt change.** Medical Service 2 breaks at t=33;
- **Parameter change.** Response time of Medical Service 1 increases from 22 to 32 ms at t=55.

The plots show that both adaptation approaches deal with all types of change: the measured values of both goals follow their setpoints. As in the previous experiments, ActivFORMS requires more time to adapt to the new setpoints.

More importantly, the cost of TAS workflow execution at t=22 decreases to 10.2e with SimCA vs 10.8e with ActivFORMS. When Service 2 shuts down at t = 33, it is already barely used by SimCA because there is another combination of services that can produce the same result with lower cost. However, the ActivFORMS solution even increases the utilization of Service 2 when t is between 22 and 33. When the response time of Service 1 increases at t = 55, the difference between the workflow invocation cost is around 1e per invocation. This scenario shows that SimCA better solves optimization tasks.

### 4.3 Guarantees

By using the simplex method, SimCA guarantees optimal cost in TAS without violating the failure rate and response time goals. Simplex has proven to be a practical and fast algorithm for solving this kind of optimization problems [5].

The control-theoretical guarantees provided by SimCA are divided into four main categories: asymptotic stability, steady-state error, settling time and overshoot. If a closed-loop system is asymptotically stable, it reaches the proximity of the setpoint $s_i$. If the system has zero steady-state error, its setpoint $s_i$ is reached after a certain time and $O_i(k) = s_i(k), k \geq K$. The amount of time $K$ after this happens is called settling time. If the controlled value exceeded the setpoint before reaching a stable area, this is called overshoot and should be avoided.

The control-theoretical guarantees provided by SimCA are confirmed by the data shown on the Figures:

- The control system is asymptotically stable and converges without overshooting, since it is designed to have only a single pole $p$ which belongs to the open interval $(0, 1)$;
- According to the system output equation of SimCA [16], the output $O_i$ during steady-state equals $s_i$ which leads to a zero steady-state error: $\Delta e = O_i - s_i = 0$. The absence of a steady-state error can be observed on the performance plot of Figure 5 when $t > 15$;
- The settling time $K$ of a unit step of every controller $i$ depends on the pole $p_i$ and a constant $\Delta s_i$ chosen by the system engineer: $K = \frac{\ln s_i}{\ln p_i}$. According to [10, p.85], the commonly used value of $\Delta s$ is 0.02 (2%). Hence $K = \frac{\ln 0.02}{\ln 0.02} = 193.6$. This means that changing the response time from 26 to 28 (step of amplitude 0.2) would take around 193.6*0.2 ≈ 40 adaptation steps. This guarantee can be observed on the performance plot of Figure 8 when $t$ is between 20 and 24;
Due to the nature of the simplex method, SimCA will only work when the setpoint of every goal lays between minimal and maximal values of that goal: \[ \min_i \leq s_i \leq \max_i \]. Therefore, when having an infeasible goal, a system with SimCA will not converge to the closest feasible value for that goal. Instead, the user will be notified that the task is not solvable and the change point detection mechanism will cause an infinitely loop of identification phases, see Figure 9. On the contrary, ActivFORMS will adapt the system output so that it converges to the closest feasible goal value.

\[ \Delta t = 1000 \text{ inv.} \]

Figure 9: SimCA vs ActivFORMS with infeasible goal

The ActivFORMS approach provides offline and online guarantees on the system behaviour. The offline guarantees come from the verification of the formal model through TCTL properties at the design time with the Uppaal model checker; verified properties are: reachability, safety, liveness, and deadlock freeness [1].

To achieve the guaranteed cost optimality required by TAS, we first implemented the utility function algorithm as a part of the planner component of a MAPE-K loop. Then, we determined the lowest value of cost that does not violate the goal failure rate and response time with the help of formal offline verification of the following safety property:

\[ A[] \ (gCost = MIN_VALUE) \implies (measuredFR < gFR \ \&\& \ measuredRT < gRT) \]

The system parameters and goals for verification were taken from Table 1. The MAPE-K model is also verified to guarantee the correctness of the algorithm’s functionality. E.g., to guarantee that the system model is deadlock free, i.e. it does not have erroneous states and the system does not get stuck in any particular state, Uppaal provides a special formula:

\[ A[] \not\text{deadlock} \]

The following liveness property guarantees that whenever the planning behavior is invoked to create a plan, then eventually a plan is executed.

Planning.CreatePlan --> Execution.PlanExecuted

The runtime guarantees of ActivFORMS are provided in two ways. First, the model that was formally verified offline is directly executed by the virtual machine at runtime so these guarantees are preserved at runtime. Second, as offline verification is limited to the input provided by the verification models, ActivFORMS allows to continue verification of properties at runtime and inform the user about violations. We refer the interested reader to [11] for details.

and \[ \Delta t = 1000 \text{ invocations, 4 time steps on the graph equals to 40 adaptation steps} \]

\[ \Delta t = 1000 \text{ inv.} \]

Figure 10: SimCA vs ActivFORMS with a constant disturbance (\( \Delta t = 1000 \text{ inv.} \))

In the studied TAS scenarios we used both types of runtime guarantees provided by ActivFORMS. The direct execution of the verified model allows to guarantee the correctness of the adaptation mechanism implementation; the runtime verification mechanism of ActivFORMS guaranteed that the minimal cost, previously determined offline, does not lead to violation of the failure rate or response time goals at runtime. To insure the latter, we added the following runtime goals:

\[ G1: A[] \ (measuredFR < 0.9 \times gFR \ \&\& \ measuredRT < 0.9 \times gRT) \]

\[ G2: A[] \ (measuredFR > 0.9 \times gFR \ \&\& \ measuredRT > 0.9 \times gRT) \]

Goal \( G1 \) assures that the failure rate and response time of TAS do not exceed their goals. Goal \( G2 \) assures that the values of both goals will not drop lower than 90% of their goals, i.e. the system will not waste resources. In case of a runtime goal violation, the cost setpoint \( gCost \) is adapted accordingly: for \( G1 \) violation \( gCost \) is increased by the cost increment \( \Delta C \), for \( G2 \) violation \( gCost \) is decreased by \( \Delta C \).

Changing \( \Delta C \) allows trading-off the speed of the system reaction to runtime changes (settling time) for the amplitude of system outputs oscillations around the goal value (accuracy).

4.4 Disturbance handling

Throughout the experiments discussed in Section 4.2, both approaches handled randomly distributed measurement disturbances caused by the changes of service parameters at runtime. Different to ActivFORMS, SimCA allows to formally evaluate the amount of disturbance the system can withstand.

According to the PBM approach [8] that lays at the core of SimCA, the amount of disturbance the system can withstand \( \Delta(d) \) by using a PBM controller can be estimated as follows: \( 0 < \Delta(d) < \frac{\Delta p}{p} \). This means that the value of the pole \( p \) defines how SimCA will react to disturbances. For \( p = 0.98 \) that was used in most experiments, the measurement can be inaccurate by a factor of 100, and the controller of SimCA will still adapt the system to follow the goals.

However, as mentioned in Section 4.3, the simplex method will not be able to reach an infeasible goal. Hence, the measurement inaccuracy on values of goal \( i \) that SimCA can with-
stand is: $\min_i \leq \Delta(d) \leq \max_i$. This property of SimCA can be observed on Figure 7 after $t = 40$: the reliability output reaches a value that is higher than maximal achievable value for a TAS workflow which causes a re-identification phase.

When it comes to constant disturbances, both approaches successfully perform adaptation. In the scenario shown on Figure 10, there is a constant response time measurement disturbance of $+3$ ms (e.g., the sensor shows $29$ ms instead of $26$ ms). As in the previous experiments with the same pole and cost increment, SimCA converges to the setpoint faster. It is notable that ActivFORMS achieves better cost by slightly violating the performance goal.

5. DISCUSSION

Both SimCA and ActivFORMS successfully solved the adaptation problem. The choice between these approaches depends on the particular scenario. When it comes to formal guarantees, both approaches provide the main guarantee required from adaptation, i.e., to minimize the cost without violating performance and reliability goals. SimCA guarantees this by using the simplex method and ActivFORMS verifies the solution optimality offline. However, at runtime SimCA performs better because offline system validation of ActivFORMS relies on particular system properties that may not hold online.

Other formal guarantees provided by the two approaches are different. With SimCA it is possible to formally prove a number of system properties, such as stability, settling time, amount of disturbance the system withstands, etc., which do not depend on the particular system parameters. On the contrary, with ActivFORMS these properties are inherent to the underlying algorithm, such as a utility function that was used in our study, and do not come from the design of the adaptation mechanism. With ActivFORMS it is possible to formally verify these properties of the algorithm on a particular set of system parameters by exploring the whole state space. However, trying to verify the TAS system with all possible combinations of service parameters will lead to an explosion of the state space. This is compensated by runtime verification.

On the other hand, with ActivFORMS the correctness of the implementation of adaptation mechanism can be formally proven, in particular the absence of erroneous states and correct interaction between adaptation components.

6. CONCLUSIONS

In this paper we presented a comparative evaluation of the two different approaches for self-adaptation: SimCA which is based on control theory and linear optimization, and architecture-based ActivFORMS equipped with a utility function. The study was performed using the TAS exemplar. The analysis of adaptation results have shown that both approaches can deal with multiple goals and provide guaranteed optimality with respect to an additional goal. However, SimCA achieves better results in the presence of runtime changes as it does not rely on data verified at design time. At the same time, ActivFORMS is a good choice for systems that require low settling time.

Except optimality, the two adaptation approaches offer different guarantees. The design of SimCA adaptation mechanism, such as the pole value or the system output equation, allows to formally prove the properties of underlying system and guarantee that they will hold at runtime independent of system parameters. ActivFORMS allows formal verification of system properties based on the particular input data. Runtime verification allows complementary verification when the system parameters change. An important feature of ActivFORMS is that it allows to formally guarantee the functional correctness of the implementation of adaptation algorithm.

This work is a first step towards understanding the effectiveness and formal power of different adaptation mechanisms. As a part of future efforts, we want to compare other adaptation approaches, such as QoSMOS [2] to SimCA and ActivFORMS. We are also planning to test the adaptation mechanisms on different types of systems and scenarios.
